Lecture 13: Data transformations

Criminology 250

Prof Maria Cuellar

University of Pennslyvania

My diagnostic plots look bad, now what?

You could try using a more complex model. But first, try transforming the data **before** fitting it, by using an invertible tranformation (powers and logs) of your response variable (\$y\$). Then, you can transform x as* well.

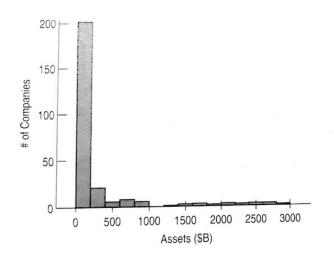

- Transforming a variable involves using a mathematical operation to change its measurement scale. This is useful in linear regression because you can use the transformation to fit a model better, and then untransform the results.
- There are many types of transformations, but the most common ones are taking the log of y and squaring y.

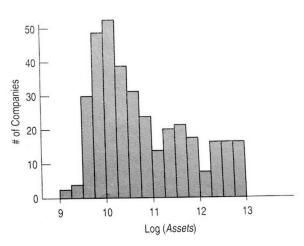

Transformations to achieve linearity

Method	Transform	Regression equation	Predicted value (ŷ)
Standard linear regression	None	$y = b_0 + b_1 x$	$\hat{y} = b_0 + b_1 x$
Exponential model	DV = log(y)	$\log(y) = b_0 + b_1 x$	$\hat{y} = 10^{b_0 + b_1 x}$
Quadratic model	DV = sqrt(y)	$sqrt(y) = b_0 + b_1 x$	$\hat{y} = (b_0 + b_1 x)^2$
Reciprocal model	DV = 1/y	$1/y = b_0 + b_1 x$	$\hat{y} = 1 / (b_0 + b_1 x)$
Logarithmic model	IV = log(x)	$y=b_0+b_1log(x)$	$\hat{y} = b_0 + b_1 log(x)$
Power model	DV = log(y) $IV = log(x)$	$log(y)= b_0 + b_1 log(x)$	$\hat{y} = 10^{b_0 + b_1 log(x)}$

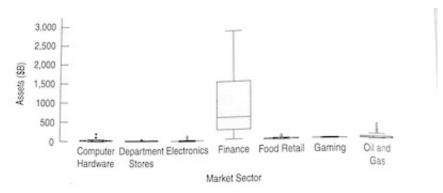

The last column shows the "back transformation" equation used to restore the dependent variable to its original, non-transformed measurement scale.

How do transformations look in the EDA?

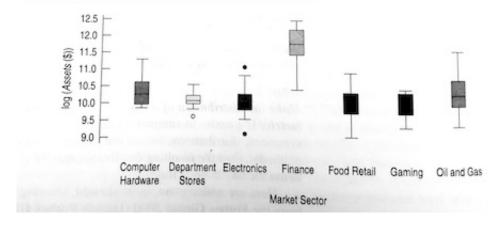

How do transformations look in the EDA?

Taking logs makes the individual boxplots more symmetric and gives them spreads that are more nearly equal. When a re-expression simplifies the structure in several groups at once, it seems to be a natural choice for those data.

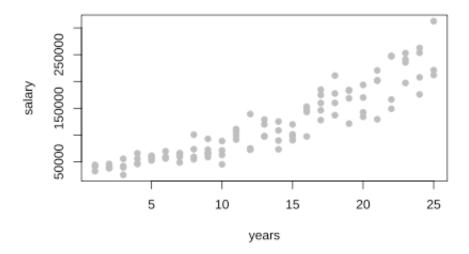

Example

How transforming the data can help fix the diagnosics

Let's look at some (fictional) salary data from the (fictional) company Initech. We will try to model salary as a function of years of experience. Here is the scatterplot:

Salaries at Initech, By Seniority

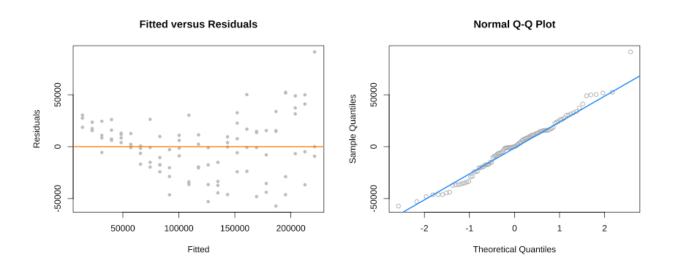

Untransformed linear model

This model appears significant, but does it meet the model assumptions?

```
##
## Call:
## lm(formula = salary \sim years, data = initech)
##
## Residuals:
##
     Min
             10 Median
                           30
                                 Max
## -57225 -18104 241 15589 91332
##
## Coefficients:
              Estimate Std. Error t value Pr(>|t|)
##
                            5750 0.922 0.359
## (Intercept)
                  5302
## years
                              389
                                  22.200
                  8637
                                           <2e-16 ***
## ---
## Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 '
##
## Residual standard error: 27360 on 98 degrees of freedom
## Multiple R-squared: 0.8341, Adjusted R-squared: 0.832
## F-statistic: 492.8 on 1 and 98 DF, p-value: < 2.2e-16
```

Diagnostics don't look so good

From the fitted versus residuals plot it appears there is non-constant variance. Specifically, the variance increases as the fitted value increases.

Variance-stabilizing transformation

 We will now use a model with a log transformed response for the Initech data,

$$log(Y_i) = \beta_0 + \beta_1 x_i + \epsilon_i.$$

 Note, if we re-scale the model from a log scale back to the original scale of the data, we now have

$$Y_i = exp(eta_0 + eta_1 x_i) exp(\epsilon_i),$$

• Fitting this model in R requires only a minor modification to our formula specification.

 $initech_fit_log = lm(log(salary) \sim years, data = inite$

Scattertplots of the transformed data

Left: Transformed y vs. x with regression line that was fit to transformed y, Right: Untransformed y vs. x with regression line that was fit to transformed y.

Diagnostics look good now

It appears the constant variance assumption is no longer violated.

How to interpret transformed regression outcome?

```
##
## Call:
## lm(formula = log(salary) \sim years, data = initech)
##
## Residuals:
      Min
              1Q Median
                             3Q
                                   Max
## -0.57022 -0.13560 0.03048 0.14157 0.41366
##
## Coefficients:
           Estimate Std. Error t value Pr(>|t|)
##
## years
## ---
## Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 '
##
## Residual standard error: 0.1955 on 98 degrees of freedom
## Multiple R-squared: 0.8915, Adjusted R-squared: 0.890
## F-statistic: 805.2 on 1 and 98 DF, p-value: < 2.2e-16
```

How to interpret transformed regression outcome?

• The transformed response is a linear combination of the predictors:

$$log(\hat{y}(x)) = \hat{\beta}_0 + \hat{\beta}_1 x = 10.848 + 0.079x,$$

 If we re-scale the data from a log scale back to the original scale of the data, we now have

$$\hat{y}(x) = exp(\hat{eta}_0)exp(\hat{eta}_1x) = exp(10.848) + exp(0.079x).$$

- We see that every one additional year of experience is associated with average salary increases of exp(0.079)=1.082 times. We are now multiplying, not adding.
- Prediction: If you want to make a prediction, you can plug in the value of x that you're interested in to see what the corresponding predicted value of y would be, according to your model. Suppose we'd like to know, for x=10 years, what is fitted y, salary?

$$exp(10.848) + exp(0.079x) = exp(10.848) + exp(0.079 *10)$$

Steps to perform a transformation to achieve linearity

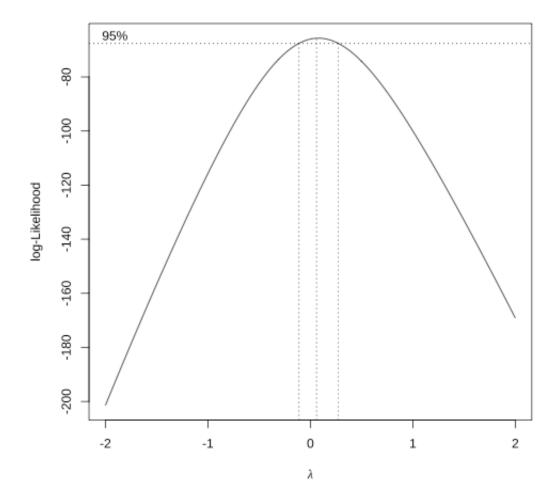

- 1. Conduct a standard regression analysis on the raw data. Draw the residuals vs. x and calculate the coefficient of determination, \mathbb{R}^2 . If the data look linear, do not transform it. If it does not, continue.
- 2. Choose a transformation method. Transform the independent variable, dependent variable, or both.
- Repeat step 1, by running the regression analysis on the transformed data. If the transformed data looks more linear, the transformation was successful. Congratulations! If not, try a different transformation method.
- 4. Now that you've transformed the data, how do you interpret the coefficients? You need to "undo" the transformation. See column 4 of the table in the last slide. For example: Say you transform x to x^2 . Now instead of reading the regression outcome as "for a 1 unit higher x, y is higher by b_1 units," you'll say "for a 1 unit higher x, y is higher by b_1 units".

the relationship between the independent variable (x) and $\frac{14}{20}$

How to Perform a Transformation to Achieve Normality (Box-Cox)

- Trial and error: In practice, these methods need to be tested on the data to which they are applied to be sure that they increase rather than decrease the linearity of the relationship.
- It's hard to know which transformation is best for your data. Thankfully, there's a test that can serve as a guide: the Box-Cox method.
- The Box-Cox transformation is named after statisticians George Box and Sir David Roxbee Cox who collaborated on a 1964 paper and developed the technique.

The Box-Cox method

Box Cox transformations

Common Box-Cox Transformations		
Lambda value (λ)	Transformed data (Y')	
-3	$Y^{-3} = 1/Y^3$	
-2	$Y^{-2} = 1/Y^2$	
-1	Y ⁻¹ = 1/Y ¹	
-0.5	$Y^{-0.5} = 1/(\sqrt{(Y)})$	
0	log(Y)**	
0.5	$Y^{0.5} = \sqrt{(Y)}$	
1	$Y^1 = Y$	
2	Y ²	
3	γ ³	

^{**}Note: the transformation for zero is log(0), otherwise all data would transform to $Y^0 = 1$.

Transforming the right-hand-side of the equation

- You can also transform x by taking the log. Here, the coefficient is the estimated percent change in your dependent variable for a percent change in your independent variable.
- Or, you can add more variables to the right-hand-side of the equation, e.g.

$$Y_i = eta_0 + eta_1 x_i + eta_2 x_i^2 + \epsilon_i.$$

Now the response y is a linear function of "two" variables: x and x squared.

 To interpret this we need to use multiple linear regressio, which we haven't studied yet.

ANOVA

- You can think of ANOVA (analysis of variance) as a more general version of the t-test, or a special case of linear regression in which all covariates are factors (i.e. categorical variables).
- Question: Is there a significant association between race and birthweight?

```
## # A tibble: 3 × 3
## race mean.bwt se.bwt
## <fct> <dbl> <dbl>
## 1 white 3103 74
## 2 black 2720 125
## 3 other 2805 88
```

- It looks like there's some association, but we don't yet know if it's statistically significant.
- Note that if we had just two racial categories in our data, we could run a t-test. Since we have more than 2, we need to run a 1-way analysis of variance (ANOVA).

ANOVA

 Terminology: a k-way ANOVA is used to assess whether the mean of an outcome variable is constant across all combinations of k factors. The most common examples are 1-way ANOVA (looking at a single factor), and 2-way ANOVA (looking at two factors).
